18 Work-Family Typologies and Mental Health Among Women
19 in Early Working Ages

20

21 **Abstract**

22 Better mental health is observed among women with a partner, children, or employment as compared
23 with women without a partner, children, or employment, respectively. Moreover, women who fulfill all
24 three roles are generally healthier than those with fewer roles. Because of significant changes in work-
25 family life constellations over age, understanding these health differentials requires a life course
26 approach. We linked work-family trajectories to mental health in mid-life for Finnish women using
27 longitudinal registry data. Panel data from an 11% random sample of the population residing in
28 Finland in any year between 1987 and 2007 and followed up until 2013 were used. Work-family
29 combinations were based on partnership status, motherhood status, and employment status.
30 Purchases of prescribed psychotropic medication were used as a measure of mental health. We used
31 sequence analysis to identify 7 distinct groups of women based on their work-family trajectories
32 between ages 20 to 42 years. The associations of typologies of trajectories with mental health at age
33 43 years were estimated with logistic regression models. Compared to employed mothers with a
34 partner, all other women were more likely to have purchased any psychotropic medication at age 43;
35 especially women without a partner, children or employment and lone mothers had worse mental
36 health. These disadvantages remained after controlling for psychotropic medication purchases earlier
37 in life (to account for potential health selection). Adjusting for age at motherhood did not contribute
38 to the better mental health of employed mothers with a partner. Women combining partnership,
39 motherhood, and employment during early working ages had better mental health later in life than
40 women with other work-family trajectories even after adjusting for mental health earlier in life.
41 Interventions to improve the mental health of women living alone in mid-life, including lone mothers,
42 and individuals without employment, may be needed.

47

48 Ethics approval

49 The use of the data for research purposes has been approved by the ethical committees of the Finnish

50 register authorities: Statistics Finland (permission 'TK-53-1519-09') and the Social Insurance Institution

51 of Finland (permission 'Kela 36/522/2010').

52

53

54

55 Introduction

56

57 Individuals living with a partner, who have children or who are employed generally have lower
58 mortality rates, better health, and engage in healthier behaviors than individuals without a partner,
59 without children in the family and without employment, respectively.¹⁻³ Previous studies also reported
60 mental health benefits of marriage and cohabitation, suggesting that the mental health of individuals
61 living with a partner is better than those not living with a partner.⁴⁻¹³ But mixed results have been
62 found with regards to the relationship between parenthood and mental health: some studies reported
63 worse mental health among parents than non-parents,^{14,15} whereas other studies reported better
64 health^{2,16,17} or no mental health differences between parents and non-parents.^{14,18} Better mental health
65 has also been observed among employed individuals.^{3,19-22} It is found to persist across race, marital
66 status, and life course stage,^{3,22} and the longer a woman's employment, the better it is for her
67 health.^{22,23}

68

69 *Combining partnership, parenthood, and employment*

70 These different dimensions of family and work life are likely to not be independent from each other in
71 their influence on health. Combining partnership, parenthood, and employment may influence an
72 individual's health in different ways. On the one hand, having multiple roles may positively influence a
73 woman's health (*the role accumulation hypothesis*); as employment provides social support and more
74 financial independence, this is associated with better health.^{24,25} This hypothesis has been supported
75 by several studies,²²⁻²⁸ and the health benefits from combining multiple roles remained after
76 controlling for the selection of healthier individuals into having multiple roles.^{22,23} On the other hand,
77 the competing demands of combining employment, marriage, and parenthood, and the stress
78 resulting from that, may negatively influence health (*the multiple role hypothesis*).^{24,25,29} Nevertheless,
79 (mental) health may largely be affected by the time spent in specific work-family states; their positive
80 or negative health effects may be cumulative. For example, the (mental) health disadvantage

81 experienced by women who were a lone mother for most of their early working life may be different
82 than that experienced by lone mothers whom (re)partnered quickly and were thus able to benefit from
83 having a partner. Adopting a life course approach is therefore important as work-family life changes
84 over an individual's life, but also the meaning of certain work-family combinations may change over
85 the life course.

86

87 *Women's work-family life and health later in life*

88 The link between work-family trajectories and health outcomes later in life has received increasing
89 attention in recent years. For example, findings from a study by Nordenmark²⁷ suggested that the
90 number of social roles an individual has, as well as an increase in this number over time, is negatively
91 associated with risk of suffering from insomnia or a long-lasting illness, or taking medication for a
92 lingering illness on a regular basis. Hewitt and colleagues³⁰ found that combining a family with no
93 employment or part-time employment was associated with better self-reported health among
94 Australian women, whereas combining children with full-time employment had a negative impact on
95 self-reported health. Using data from the Household, Income and Labour Dynamics in Australia
96 survey, O'Flaherty and colleagues³¹ found that among women, only those with a disrupted marital
97 history and high fertility had poorer physical health. Johansson and colleagues³² found no clear
98 differences in health and well-being among Swedish women with different life courses based on work
99 and family activities during early working ages. Findings from a study by Kostianen and colleagues²⁸
100 suggest that among Finnish women aged 30 to 49 years having multiple roles was associated with
101 good self-rated health. Lacey and colleagues³³ found that married mothers with weak ties to the labor
102 market had lower self-reported well-being, even after adjusting for well-being at childhood, using
103 data from the 1946 British birth cohort. Additionally they found that life satisfaction was lower among
104 women with weaker ties to the labor market, as well as women without children. Findings from
105 another study by Lacey and colleagues³⁴ also based on data from the 1946 British birth cohort suggest
106 that among women with full-time employment having a family earlier or later did not result in

107 differences in metabolic profile in mid-life. Using data from the 1946 British birth cohort, McMunn and
108 colleagues³⁵ found that women with fewer roles than those of employee, spouse, and mother
109 reported worse health. Using data from the 1958 British birth cohort, Lacey and colleagues³⁶ found
110 that women with work-family trajectories characterized by early entry into parenthood and weak work
111 ties were more likely to have chronic inflammation in mid-life than men and women who had children
112 later or who had stronger ties to paid work. Using the same dataset, McMunn and colleagues³⁷ found
113 that women in work-family trajectories characterized by earlier transitions to family life had higher
114 metabolic risks, irrespective of the strength of their ties to the labor market or their marriage stability.
115 McMunn and colleagues³⁸ found in another study that role quality explained the poorer subjective
116 health among lone mothers, but not among long-term homemakers or childless women, using data
117 from the 1946 British birth cohort. Using data from the English Longitudinal Study on Aging, Benson
118 and colleagues³⁹ found that women with a family who took a long career break were more likely to
119 report depressive symptoms but had a lower mortality rate, whereas women who took shorter career
120 breaks were less likely to report disability later in life. Using data from the Health and Retirement
121 Study in the United States, Sabbath and colleagues⁴⁰ found higher mortality risks among single
122 nonworking mothers, single working mothers and married nonworking mothers, compared to married
123 mothers who stayed home for only a short period before returning to work. Sabbath and colleagues⁴¹
124 additionally found that women who experienced spells of single motherhood between ages 18 and 50
125 years had the highest mortality risk, particularly previously married women who became single
126 mothers later in life and who had low job control. Using data from the Survey of Health, Aging and
127 Retirement in Europe and the Health and Retirement Study in the United States, Van Hedel and
128 colleagues⁴² found that compared to working married mothers, women with other work-family
129 trajectories were more likely to have been diagnosed with heart disease (working single mothers) and
130 stroke (working single mothers and married mothers who returned to work after some non-
131 employment).

132 Most studies linking work-family trajectories and health have focused on health at older ages
133 and health outcomes other than mental health using self-reported data. A selection of studies
134 included work-family trajectories with annual measures^{31-34,36,37,39-43} or included previous health
135 measures^{31,33-37,39,43} to account for possible health selection into specific work-family life courses.

136

137 *Aim of this study*

138 The aim of this study is to investigate mental health differences of women in mid-life who experienced
139 different work-family trajectories in early working ages, using longitudinal Finnish registry data. Our
140 study adds to the current literature in multiple ways. First, we used longitudinal registry data that does
141 not rely on self-reported data and only suffers from attrition due to death and emigration, but not
142 non-response. Second, work-family trajectories with annual information during the follow-up is
143 available, allowing us to look at the overall trajectory rather than specific work-family combinations at
144 certain ages. Third, we control for pre-existing health, thus taking into account some of the possible
145 health selection effects into specific work-family trajectories. This study focused on women, because
146 women are most likely to feel competing work and family life demands. Even though female labor
147 force participation has increased substantially in recent decades, women still take up most of the core
148 housework work and spend more time with the children than do men.^{44,45} We used sequence analysis
149 to construct work-family typologies based on trajectories observed at ages 20 to 42 years and logistic
150 regression models to study the association of these typologies with mid-life mental health at age 43.

151

152 Data and methods

153

154 *Sample*

155 An 11% random sample representative of the population residing in Finland at the end of any of the
156 years 1987 to 2007, followed until the end of 2013, was used. This sample was linked to data from
157 official registries, such as the labor market data file and medication records, on an individual level by

158 using a unique personal identification code. All purchases of any prescribed medication were recorded
159 from 1995 onwards, including purchase dates, the type of drug, and the amount purchased. We
160 restricted the sample to women born between January 1 1967 and December 31 1970 (n=14997
161 women), to allow for the estimation of work-family trajectories between ages 20 to 42 for women
162 from multiple birth cohorts. In total, 1443 women were missing information on at least one year
163 between ages 20 to 42. Of these women, 172 died during the follow-up period and 1271 women were
164 not living in Finland for at least one year resulting in a gap in their follow-up. After excluding these
165 women, our sample consisted of 13554 women with fully observed work-family trajectories.
166 Descriptive information for selected variables for women included and excluded from the sample is
167 provided in Table A of the supplemental materials.

168

169 *Mental health*

170 Mental health was measured based on purchases of prescribed psychotropic medication. In our study,
171 psychotropic medication included antidepressants (Anatomical Therapeutic Chemical [ATC] codes⁴⁶
172 starting with N06A), antipsychotics (ATC codes starting with N05A), and anxiolytic/sedative/hypnotic
173 (ASH) medication (ATC codes starting with N05B or N05C). The outcome was binary; i.e. whether or
174 not a woman purchased at least one prescription of psychotropic medication in the year she turned 43
175 years. For example, this would be purchasing at least one psychotropic medication in 2010 for a
176 woman born in 1967, at least one purchase in 2011 for those born in 1968, and so on. Mental health
177 earlier in life (at ages 28 to 32), representing possibly pre-existing mental health problems, was
178 measured similarly.

179

180 *Work-family variables*

181 Work-family trajectories were based on three dimensions of work and family life: partnership,
182 parenthood, and employment. We defined partnership status as living with a married or cohabiting
183 partner. Individuals were identified as cohabiting when they lived in the same dwelling as their partner

184 of opposite sex, who was not a married spouse or a sibling, and with whom the age difference did not
185 exceed 15 years. Individuals not in a partnership included those living with at least one adult other
186 than a partner (e.g., a parent, friend or sibling), those not living with other adults (e.g., living alone or
187 lone parents), and those with an unknown living arrangement status. Parenthood status was defined
188 as having at least one co-resident child under the age of 18 years in the family. Employment status
189 was defined as being employed at the time of the census in the preceding year. Individuals not in
190 employment included those unemployed, but also students, pensioners, and others (including
191 unknown, conscripts and conscientious objectors). These work-family variables were annually
192 measured between 1987 and 2012, and combined into eight possible work-family combinations based
193 on the values of each of the three variables.

194

195 *Educational attainment*

196 Educational attainment was based on the highest degree obtained by the individual and divided into
197 four categories: only compulsory education, upper secondary or less education, lower tertiary
198 education, and higher tertiary or more education. Educational attainment at age 42, i.e. end of follow-
199 up, was used to account for completed education, as we expect educational attainment to be related
200 to psychotropic medication purchases, work and family factors, and thus also to the work-family
201 trajectories.

202

203 *Sequence analysis*

204 Sequence analysis, a methodological framework to analyze trajectories and processes,^{47,48} was used to
205 identify common work-family typologies in our data. For each woman, we constructed a work-family
206 trajectory between ages 20 to 42 years based on the eight possible combinations of partnership,
207 parenthood and employment status. The calendar years for these trajectories differed by birth year;
208 for a woman born in 1967, her trajectory started in 1987 and ended in 2009, whereas the trajectory for
209 a woman born in 1970 started in 1990 and ended in 2012 (Table B of the supplemental materials).

210 Sequence analysis uses the timing of each work-family combination, the order of work-family
211 combinations within a trajectory, and the duration an individual remained in a specific work-family
212 combination to derive distinct clusters of women with similar work-family trajectories. Of the 13554
213 women in our sample, 12801 women (94.4%) had distinct work-family trajectories.

214 The distance between the work-family trajectories of any two women in our sample was
215 computed by Optimal Matching, which defines the distance between any two trajectories in terms of
216 the minimum cost of transforming one individuals' trajectory to match another individual's trajectory.
217 We used "Partitioning Around Medoids" (PAM) to estimate cluster membership for every woman in
218 our sample (for any number of possible clusters between 2 and 15). As PAM depends upon the initial
219 choice of medoids (representative objects within a cluster) and could lead to less optimal results,
220 results from a hierarchical cluster method were used to initialize PAM and improve the quality of the
221 clustering.⁴⁹ We then estimated several cluster quality measures (Table C of the supplemental
222 materials) to determine the optimal number of clusters.^{49,50} Ideally, work-family trajectories of women
223 in the same cluster should be as homogenous as possible, whereas those of women in different
224 clusters should be as heterogeneous as possible. The cluster quality measures, e.g. a low Hubert's C
225 and a relatively high Average Silhouette Width, indicated that the seven cluster solution would be
226 suitable for our sample of Finnish women. With 8 possible work-family combinations at any one point
227 in time, the 7-cluster solution, we believe, provides meaningful typologies that are also distinctively
228 different from the other typologies. The 7 work-family typologies found are: 1. Employed women with
229 a partner, who had children in their 20s; 2. Employed women with a partner, who had children in their
230 30s; 3. Mothers with a partner, who stayed home before re-entering employment; 4. Lone mothers
231 (employed and not employed); 5. Employed women with a partner, but without children; 6. Employed
232 women without a partner or children; and 7. Women without a partner, children or employment. A
233 graphical representation of the most common work-family combination at each age between 20 and
234 42 years for the women in each of these seven work-family typologies is shown in Figure 1. Note that
235 the typologies were named based on a generalization of all work-family trajectories within a typology.

236 However, variation in work-family trajectories among women in each typology exists (Figures A and B
237 of the online supplemental materials).

238

239 [Figure 1 here]

240

241 Next, a logistic regression model was used to estimate whether the likelihood of having purchased at
242 least one prescription of psychotropic medication in the year that the woman turned 43 years differed
243 between women in the 7 work-family typologies (Model 1). Model 2 was adjusted for educational
244 attainment, as the timing of employment, family decisions and mental health are likely to depend
245 upon a woman's educational level. In Model 3, multiple measures of psychotropic medication
246 purchases earlier in life were added to control for prior differences in mental health. We used
247 purchases at ages 28 to 32 years as these were available for all women in our sample as the
248 medication data started in 1995. Both the sequence analysis (WeightedCluster version 1.2-1⁴⁹,
249 TraMineR version 2.0-8⁵⁰) and the logistic regression models were done in R Studio version 1.1.453
250 with R version 3.3.3.

251

252 Results

253

254 *Distribution of work-family typologies, educational attainment, and psychotropic medication purchases*
255 *at age 43*

256 Overall, two thirds of the women in our sample were classified as employed women with a partner
257 who had children (66.0%, typologies 1 to 3, Table 1); 28.2% had children in their 20s (typology 1),
258 23.2% had children in their 30s (typology 2), and 14.6% stayed home before re-entering employment
259 after having children (typology 3). The least common typology was that of women without a partner,
260 children or employment (5.0%, typology 7). The remaining thirty percent was relatively evenly
261 distributed over the remaining typologies; about a tenth of our sample were classified as lone mothers

262 (9.4%, typology 4), employed women with a partner but without children (9.1%, typology 5), or
263 employed women without a partner or children (10.3%, typology 6).

264

265 [Table 1 here]

266

267 Compared to lower educated women, women with higher educational attainment were more
268 likely to have been employed with a partner who had children in their 30s (typology 2); for example,
269 40.2% of the women with higher tertiary or more education were in this typology, compared to only
270 9.3% of the women with only compulsory education. Similarly, being an employed woman without a
271 partner or children (typology 6) was more common among higher educated women than those with
272 less education. Contrarily, being a mother without a partner who stayed home before re-entering
273 employment (typology 2), a lone mother (typology 4), or not having a partner, children or
274 employment (typology 7) was more common among women with less education than those with
275 higher educational attainment. For example, 18.3% of women with only compulsory education were
276 lone mothers, whereas only 3.8% of women with higher tertiary or more education were in this
277 typology.

278 Overall, 17.0% of all women had at least one purchase of psychotropic medication in the
279 calendar year they turned 43 years. However, this prevalence differed for women in different work-
280 family typologies. It was highest among women without a partner, children or employment (41.0%;
281 typology 7) and lone mothers (23.3%; typology 4), and lowest among employed mothers with a
282 partner (13.0% for those who had children in their 20s, typology 1; and 13.7% of those who had
283 children in their 30s, typology 2).

284

285 *Psychotropic medication purchases*

286 No difference in psychotropic medication purchases at age 43 was found between employed women
287 with a partner who had children in their 20s (typology 1) or their 30s (typology 2) in the logistic model

288 adjusting for birth year (Model 1, Figure 2). Compared to employed women with a partner who had
289 children in their 20s (typology 1), women without a partner, children or employment (typology 7) were
290 over four times as likely to have purchased psychotropic medication (odds ratio [OR]: 4.65, 95%
291 confidence interval [CI]: 3.88, 5.56), whereas lone mothers were twice as likely to have purchased
292 psychotropic medication (OR: 2.03, 95% CI: 1.72, 2.38; typology 4). The women in the remaining three
293 categories were all approximately 40% more likely to have purchased psychotropic medication at age
294 43 than employed women with a partner who had children in their 20s (typology 1). These results only
295 changed slightly after adjusting for educational attainment (Model 2).

296

297 [Figure 2 here]

298

299 Adjusting for previous purchases of psychotropic medication at ages 28 to 32 (Model 3)
300 attenuated the observed disadvantages for women in all typologies, except that of employed women
301 with a partner who had children (in their 30s). For example, the disadvantage of mothers with a
302 partner who stayed home before re-entering employment (typology 3) attenuated from 1.37 (95% CI:
303 1.18, 1.59) to 1.23 (95% CI: 1.04, 1.44). When purchases earlier in life were taken into account, the
304 initial disadvantage for employed women with a partner but without children (typology 5) attenuated
305 to non-significant.

306

307 *Purchases of antidepressants, antipsychotics, and anxiolytic/sedative/hypnotic (ASH) medication*

308 Of the three subcategories of psychotropic medication, antidepressant purchases were most common
309 (12.2%), ASH medication purchases were less common (8.0%), and purchases of antipsychotics were
310 least common (3.5%). The distributions of these subcategories of psychotropic medication by work-
311 family typology were similar to the one found for any psychotropic medication (Table 2). The ORs of
312 antidepressants and ASH medication purchases for the 7 work-family typologies were comparable in
313 magnitude to those for any psychotropic medication, but those for antipsychotics were higher.

314 Similarly, adjusting for previous psychotropic medication purchases (Model 3) attenuated the
315 observed disadvantages for women in the work-family typologies other than employed mothers with
316 a partner. Moreover, the disadvantages of employed women with a partner but without children
317 (typology 5) and employed women without a partner or children (typology 6) in terms of
318 antidepressant purchases, and the disadvantage of mothers with a partner who stayed home before
319 re-entering employment (typology 3) in terms of ASH medication purchases were attenuated to non-
320 significant.

321

322 [Table 2 here]

323

324 Discussion

325

326 *Summary of results*

327 Seven distinct work-family typologies were found for Finnish women based on partnership,
328 motherhood and employment status. Certain work-family typologies were associated with worse
329 mental health for Finnish women; all women other than employed mothers with a partner were more
330 likely to have purchased any psychotropic medication in mid-life, i.e. at age 43. Especially women
331 without a partner, children or employment and lone mothers were worse off, but also mothers with a
332 partner who stayed home before re-entering employment and employed women without a partner or
333 children were more likely to have purchased psychotropic medication in mid-life. These disadvantages
334 remained after adjusting for educational attainment and psychotropic medication purchases at ages
335 28 to 32 years, and were also found for antidepressants, antipsychotics, and ASH medication
336 separately. Age at motherhood did not seem to matter for mid-life mental health of employed
337 mothers with a partner.

338

339 *Methodological considerations*

340 A major strength of this study was the use of data on purchased psychotropic medication from official
341 medication registries, and register data on partnership, parenthood, and employment status rather
342 than using self-reported data for these measures. It therefore does not suffer from biases associated
343 with self-reported measures, such as recall bias (especially with a long follow-up), possible
344 misreporting of mental health, and loss to follow-up among those with mental health problems or
345 those without employment. Additionally, we were able to study partnerships in general and not only
346 (legal) marital status, as Finland is one of the few countries that has registry data on cohabitation
347 status going back to 1987.

348 Purchases of prescribed psychotropic medication were used as a proxy for mental health. It is
349 an objective measure and a good indicator of poorer mental health, but it is not perfect. For example,
350 not all psychiatric disorders are diagnosed, psychotropic medication may be prescribed for other
351 reasons than psychiatric disorders, and individuals who were diagnosed with psychiatric disorders may
352 not purchase their prescribed psychotropic medication.^{51,52} Drawing conclusions on overall mental
353 health based on results using purchased psychotropic medication should thus be done carefully.
354 However, the use of antidepressants without a known psychiatric morbidity tends to increase only at
355 older ages.⁵²

356 The quality measures used to determine the optimal number of clusters, indicated that
357 besides a seven cluster solution, a five or ten cluster solution would also be suitable for our data. On
358 the one hand, the five cluster solution provided a typology combining employed mothers with a
359 partner irrespective of when they had children, and a typology combining women without a partner or
360 children irrespective of whether they were employed (results available upon request). Conclusions
361 were generally similar to those of the seven cluster solution. However, by restricting the number of
362 typologies, we would have overlooked the mental health differences between employed women
363 without a partner or children and women without a partner, children or employment. On the other
364 hand, the ten cluster solution split employed mothers with a partner into four categories (rather than
365 two) based on different timings of partnership and motherhood, and it additionally distinguished

366 between lone mothers with and without employment (results available upon request). Overall,
367 conclusions were similar to those of the seven cluster solution. The ten cluster solution allowed us to
368 specifically look at lone mothers without employment, who were worse off in terms of their
369 psychotropic medication purchases, and in particular antipsychotics. However, allowing for more
370 work-family typologies mainly resulted in more categories of employed mothers with a partner, who
371 were similar in their psychotropic medication purchases. Therefore we believe that the seven cluster
372 solution provided representative typologies indicating the more (and less) disadvantaged groups of
373 women in our data.

374 One may also argue that only considering psychotropic medication purchases in the year the
375 woman turned 43 years may cover a too narrow time period for reporting mid-life mental health. To
376 check the robustness of our findings, we used a binary outcome based on having purchased at least
377 one prescription of psychotropic medication in the calendar years in which the woman turned 41 to 43
378 years. This shortened the work-family trajectories to cover ages 20 to 40 years. Based on these slightly
379 shorter work-family trajectories, we found seven very similar work-family typologies (results available
380 upon request). Overall, conclusions were very similar to those based on the original work-family
381 trajectories from ages 20 to 42 years.

382 As women have been most likely to feel competing demands of combining work and family
383 life, this study focused on their work-family trajectories and mental health. Nevertheless, men have
384 been spending more time doing core housework tasks more recently.⁴⁵ Competing demands may thus
385 play a more important role for men's mental health in recent times than it has in the past. Gender
386 differences in the association of work-family life and mental health have been shown; mental health
387 benefits of full-time employment increased over the life course for men, but women women's mental
388 health benefitted increasingly as children grow older.⁵³ Future research should therefore also consider
389 work-family trajectories of men and their association with mental health.

390

391 *Interpretation*

392 Employed mothers with a partner had better mental health than women with other work-family
393 trajectories. This finding is consistent with the role accumulation hypothesis and in line with several
394 previous studies.²²⁻²⁸ Employed women with a partner who had children in their 20s or their 30s did
395 not differ in their likelihood of purchasing psychotropic medication in mid-life. Hence, age at
396 motherhood did not seem to lead to mental health differences later in life for employed women with
397 a partner. However, selection into partnership, parenthood, and employment may have played an
398 important role in this finding; healthier individuals are more likely to marry or cohabit, become
399 parents, and be employed. Controlling for psychotropic medication purchases at earlier ages
400 attenuated some of this advantage, indicating that at least part of the association is attributable to the
401 selection of healthier women into partnerships, motherhood, and employment.

402 Mothers with a partner, who stayed home before they re-entered employment after having
403 children were more likely to have purchased psychotropic medication at age 43 years than mothers
404 who re-entered employment within a few years after having children. Being a stay-at-home mother
405 longer may have a greater influence on a woman's financial (in)dependence, may reduce social
406 networks more, and lead to greater social isolation,⁵⁴ which could result in worse mental health.
407 However, these women may have chosen to stay home longer due to (mental) health reasons,
408 therefore health selection into staying home may also play a role. Adjusting for psychotropic
409 medication purchases at ages 28 to 32 only slightly attenuated these findings, indicating that not all of
410 this association can be explained by health selection into roles.

411 Lone mothers were more likely than employed mothers with a partner to have purchased
412 psychotropic medication in mid-life. This finding is consistent with findings from other studies; for
413 example, lone mothers were more likely to report depressive symptoms,⁵⁵⁻⁵⁷ psychological distress,⁵⁸
414 or mental disability⁵⁹ than partnered mothers. Lone mothers are raising their children without the
415 support of a partner, while they may also have the additional responsibility of being the breadwinner
416 in the family. This could all lead to increased stress. Additionally, lack of employment may be even
417 more problematic for lone mothers as there is no partner to share their financial responsibilities with.

418 Therefore, one reason for the mental health difference between lone and partnered mothers may be
419 financial hardship, as lone mothers may be more likely to have less favorable financial circumstances
420 than partnered mothers.^{58,59} The exact impact of these less favorable financial circumstances on
421 differences in psychotropic medication purchases over the life course between lone and partnered
422 mothers in Finland remains to be examined.

423 Employed women with a partner but without children were more likely to have purchased
424 psychotropic medication in mid-life than employed mothers with a partner. After taking previous
425 psychotropic medication purchases into account, these differences in psychotropic medication
426 purchases were no longer observed, suggesting health selection into childlessness. As our work-family
427 trajectories only go up to age 42, this group of women without children was very diverse; it includes
428 women who may be voluntarily childless, involuntarily childless, who had children in their late 30s, or
429 who may have children in their 40s. Information on whether a woman was voluntarily or involuntarily
430 childless was not available, so unfortunately possible mental health differences between these women
431 could not be examined. However, our findings suggest that the mental health of these women
432 together is not worse than that of employed mothers with a partner after adjusting for previous
433 psychotropic medication purchases.

434 Overall, employed women without a partner or children were slightly worse off than employed
435 mothers with a partner. This is in line with extensive research stating that not having a partner may
436 have detrimental effects on an individual's health, as being in a partnership is an important source of
437 social support and could increase the economic resources available to an individual.⁶⁰ This may then
438 positively influence health.⁶¹ However, compared to women who were additionally not employed,
439 employed women without a partner or children were less likely to have purchased psychotropic
440 medication in mid-life. This finding highlights the importance of employment for one's mental health
441 in the absence of a partnership or motherhood.

442 Women without a partner, children or employment were most likely to have purchased
443 psychotropic medication at age 43. This finding is in line with the literature stating that women who

444 do not have a partner, children or employment are disadvantaged in terms of their health.^{1-13,16,19-22}
445 Health selection into partnership, parenthood, and employment partly explained this higher likelihood
446 of purchasing psychotropic medication as the disadvantage of women without a partner, children or
447 employment was strongly attenuated after adjusting for psychotropic medication purchases earlier in
448 life.

449

450 *Conclusion*

451 Overall, our results showed that compared to employed women with a partner, women with other
452 work-family trajectories had worse mental health. Among women with steady employment and stable
453 partnerships, the age of motherhood did not seem to matter for their mental health. However,
454 especially women without a partner, children or employment, and lone mothers had worse mental
455 health. Adjusting for previous psychotropic medication purchases to capture potential health selection
456 processes attenuated the mental health differences, but overall the disadvantages remained.
457 Adequate interventions and policies to improve the mental health of unpartnered women, including
458 lone mothers, and women without employment may be needed. Our results nevertheless suggest that
459 women combining partnership, parenthood, and employment had better mental health than women
460 not fulfilling all three roles.

Tables and Figures

Figure 1 – Most frequent work-family combination at each age by work-family typologies

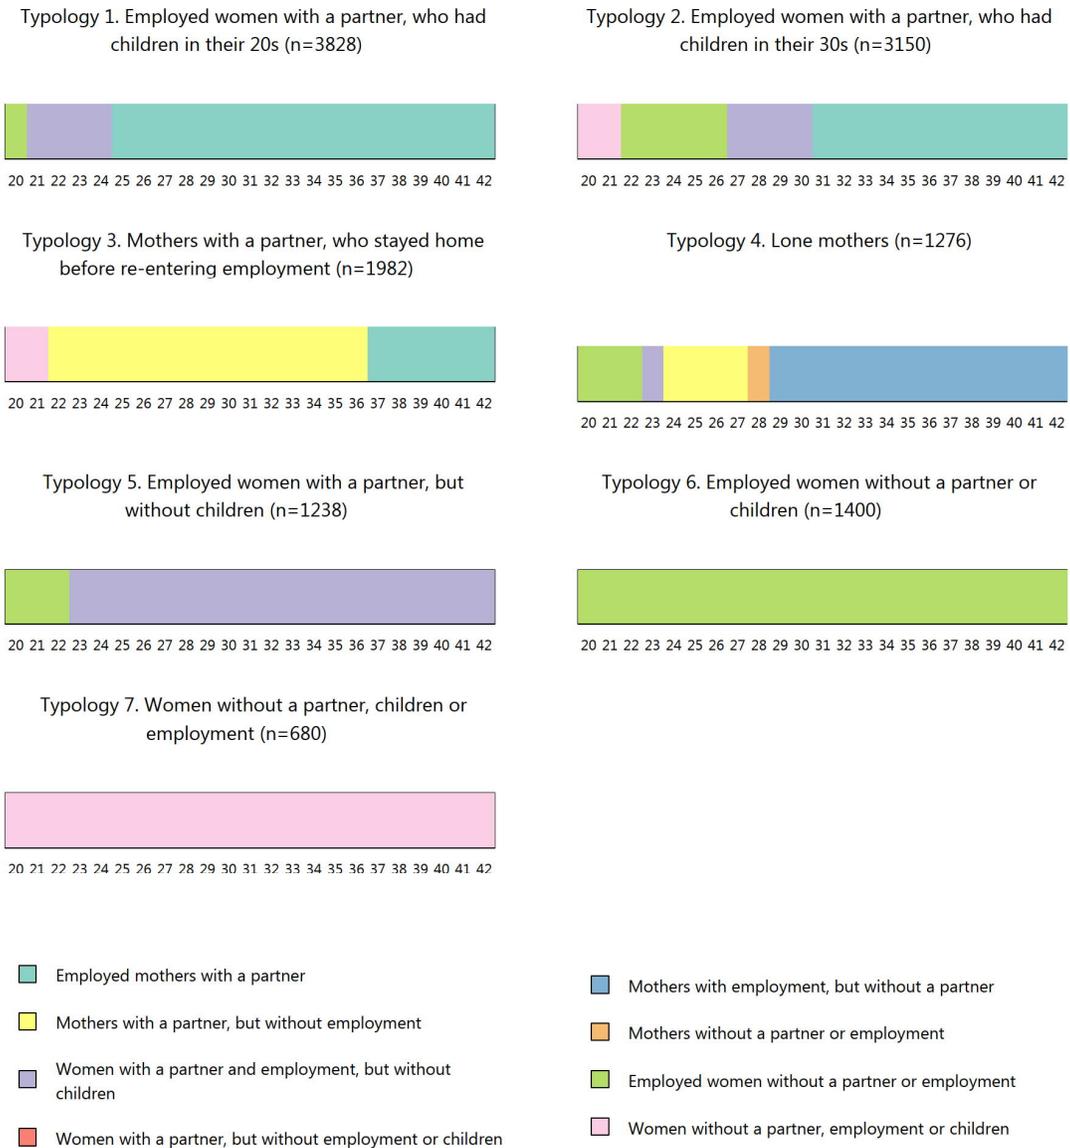

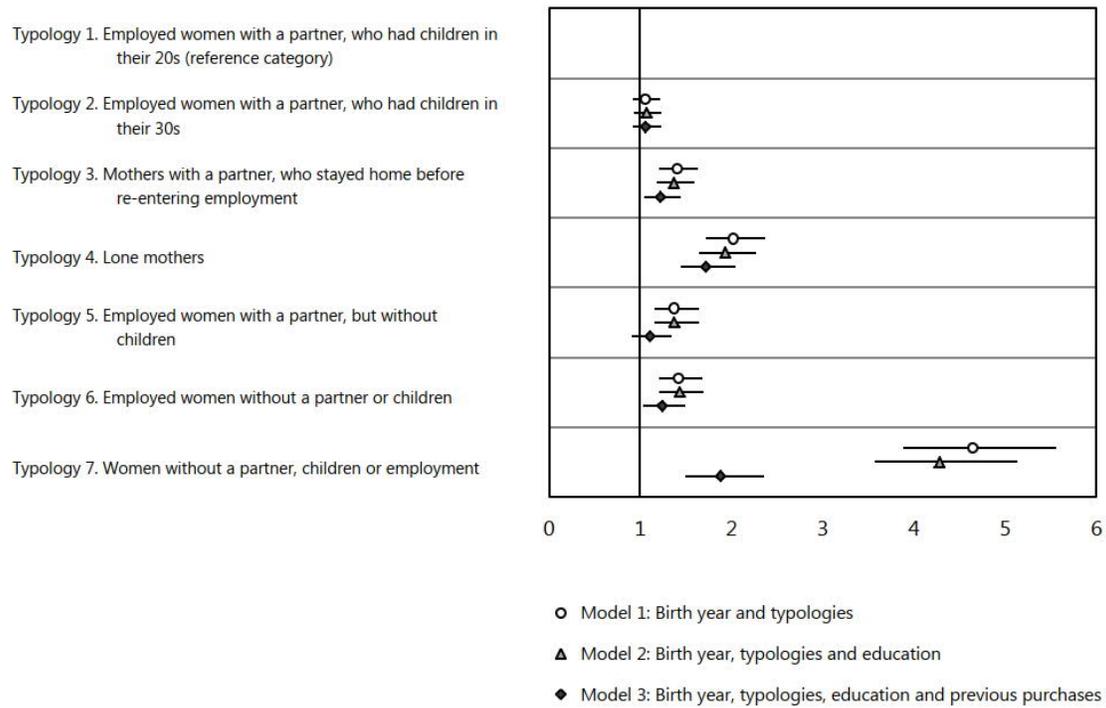

Table 1 – Distributions of the 7 work-family typologies, of educational attainment within work-family typologies, and proportions of psychotropic medication purchases by work-family typology

	All women		Typology 1.	Typology 2.	Typology 3.	Typology 4.	Typology 5.	Typology 6.	Typology 7.
	No.	%	Employed women with a partner, who had children in their 20s	Employed women with a partner, who had children in their 30s	Mothers with a partner, who stayed home before re-entering employment	Lone mothers	Employed women with a partner, but without children	Employed women without a partner or children	Women without a partner, children or employment
Distribution of work-family typologies	13554		28.2	23.2	14.6	9.4	9.1	10.3	5.0
Distribution of work-family typology by education									
Only compulsory	1199	8.8	22.9	9.3	21.6	18.3	7.3	5.8	14.8
Upper secondary	5222	38.5	30.7	15.3	18.7	11.6	8.9	8.9	5.9
Lower tertiary	4865	35.9	30.0	27.4	11.9	7.5	9.8	10.9	2.6
Higher tertiary or more	2268	16.7	21.5	40.2	7.3	3.8	9.3	15.0	2.9
Proportion of women with at least one psychotropic medication purchase in the year she turned 43 years:									
All psychotropic medication	2309	17.0	13.0	13.7	17.4	23.3	17.1	17.6	41.0
Antidepressants	1656	12.2	9.7	9.7	13.1	17.6	12.5	12.4	25.0
Antipsychotics	473	3.5	1.5	1.6	3.7	3.5	3.7	3.0	23.4
ASH medication	1091	8.0	5.9	6.2	7.9	10.9	8.8	9.4	20.1
Proportion of women with at least one psychotropic medication purchase, in the year she turned:									
28 years	701	5.2	3.1	3.2	4.8	5.2	6.1	5.9	24.0
29 years	764	5.6	3.2	3.7	5.4	6.0	6.8	5.4	26.6
30 years	851	6.3	3.5	4.0	6.5	7.9	6.8	6.4	27.5
31 years	933	6.9	4.2	4.4	6.9	8.1	8.5	6.2	29.3
32 years	981	7.2	4.6	4.1	7.3	9.9	8.4	7.6	29.0

Note. No.: Absolute number of women. %: percentage of women with medication purchases or in specific educational levels. The prevalence of antidepressants, antipsychotics, and ASH medication does not necessarily sum up to that of all psychotropic medication as women may be using more than one type at the same time.

Figure 2 – Odds ratios of having purchased psychotropic medication for women in the 7 work-family typologies

Note. Error bars represent the 95% confidence interval. Full information on point estimates and 95% confidence intervals can be found in Table D of the supplemental materials. Model 1 includes birth year and the work-family typologies. In Model 2, educational attainment at age 42 years was added. Model 3 additionally adjusts for previous psychotropic medication purchases at ages 28 to 32 years.

Table 2 – Odds ratios of psychotropic medication subcategories for the 7 work-family typologies
